4 **ABSTRACT**
5

6 Hydration forces between DNA molecules in the A- and B-Form were studied using a newly
7 developed technique enabling simultaneous in situ control of temperature and relative humidity.
8
9 X-ray diffraction data were collected from oriented calf-thymus DNA fibers in the relative
10 humidity range of 98%-70%, during which DNA undergoes the B- to A-form transition.
11
12 Coexistence of both forms was observed over a finite humidity range at the transition. The
13
14 change in DNA separation in response to variation in humidity, i.e. change of chemical potential,
15
16 led to the derivation of a force-distance curve with a characteristic exponential decay constant of
17
18 $\sim 2 \text{ \AA}$ for both A- and B-DNA. While previous osmotic stress measurements had yielded similar
19
20 force-decay constants, they were limited to B-DNA with a surface separation (wall-to-wall
21
22 distance) typically $> 5 \text{ \AA}$. The current investigation confirms that the hydration force remains
23
24 dominant even in the dry A-DNA state and at surface separation down to $\sim 1.5 \text{ \AA}$, within the first
25
26 hydration shell. It is shown that the observed chemical potential difference between the A and B
27
28 states could be attributed to the water layer inside the major and minor grooves of the A-DNA
29
30 double helices, which can partially interpenetrate each other in the tightly packed A phase. The
31
32 humidity-controlled x-ray diffraction method described here can be employed to perform direct
33
34 force measurements on a broad range of biological structures such as membranes and
35
36 filamentous protein networks.

7 **I. Introduction**
8

9 Temperature and hydration are two important environmental variables affecting the structure of
10 biological molecules, many of which undergo phase transitions as a function of relative humidity
11 and temperature. A particularly well-studied example is the distinct conformational changes of
12 the DNA double helix induced by varying relative humidity. In their very early work on
13 partially dehydrated DNA fibers, Franklin and Gosling first identified two distinct (i.e. B and A)
14 forms of DNA at different relative humidity based on x-ray fiber diffraction patterns (Franklin &
15 Gosling, 1953a,b). High salt conditions or special nucleotide sequences could lead to the
16 formation of left-handed Z-DNA (Mitsui et al., 1970; Berg et al., 2002).

27

28 In addition to changes in the molecular structure of the DNA double helix, the interaction
29 between DNA molecules, mediated by water molecules and/or ions, leads to rich mesophases
30 spanning from isotropic to 2D hexagonal and ultimately full 3D crystalline order in concentrated
31 solutions (Durand et al., 1992 ; Fuller et al., 2004; Livolant et al., 1989 ; Livolant and
32 Leforestier, 1996). The sensitivity of the DNA structure to humidity is a clear manifestation of
33 the intimate interaction of water with the internal structure of DNA. High-resolution
34 crystallographic studies on single crystals of oligo-DNA molecules confirmed the presence of a
35 “water-ribbon” winding through the minor grooves of the DNA double helix, and the water
36 molecules within the DNA were shown to be highly localized within the first hydration shell (<3
37 Å thickness) (Egli et al., 1998; Guerri et al., 1998). These oriented water molecules form
38 complex patterns that could extend as far out as the fourth hydration shell and have been
39 hypothesized to play some role in sequence recognition (Chaplin, 2006).

1
2
3
4 The interaction of overlapping hydration layers of different DNA molecules contributes
5
6
7 to the stabilization of a lattice via a repulsive hydration force. This force, which decays quasi-
8
9 exponentially with separation distance, in effect resists the removal of water between closely
10
11 packed DNA molecules. Hydration forces have been observed experimentally in a number of
12
13 systems consisting of polar surfaces and linear molecules (Leikin et al., 1993; Parsegian and
14
15 Zemb, 2011). The force-distance curves in all these systems exhibit remarkably similar
16
17 exponential decay lengths, suggesting a common origin underlying these forces. A full and
18
19 complete theoretical understanding of the hydration force has not yet emerged. It is generally
20
21 accepted, however, that the force results from the summation of weak forces related to small
22
23 perturbations of large number of water molecules by the macromolecules or surfaces (Parsegian
24
25 and Zemb, 2011).

30
31 Previous measurements on DNA hydration forces have been performed by measuring
32
33 DNA lattice constant change in response to osmotic pressure induced by mixing colloidal
34
35 molecules with DNA in solution (Parsegian and Fuller, et al., 1979; Rau et al., 1984; Rau and
36
37 Parsegian, 1992). Due to experimental limitations these measurements had been performed only
38
39 for B-DNA with surface separation typically $> 5 \text{ \AA}$. Here we describe a new technique enabling
40
41 simultaneous temperature and hydration (relative humidity) control in a sample environment
42
43 suitable for both small- and wide-angle x-ray scattering (SAXS and WAXS) studies of soft-
44
45 condensed matter and biological systems. The technique was employed to collect in-situ X-ray
46
47 diffraction data from oriented DNA fibers at precise relative humidity intervals, with DNA
48
49 molecules in either the B or A conformational states, and during the B to A transition. The data
50
51 enabled derivation of the hydration force curve in the previously un-probed surface separation

10 11 **2. Development of the compact temperature and humidity chamber for in-situ x-ray** 12 13 **diffraction**

14 15 16 2.1 Design principle

17
18 Two techniques have been widely used in humidity controlled measurements: mixing streams of
19 water vapor with dry air (Fuller et al., 2004; Sirota et al., 1988; Smith et al., 1990) and using
20 reservoirs filled with saturated salt solutions to regulate vapor pressure/humidity (van Dam et al.,
21 2002; Franklin and Gosling, 1953; Langridge et al., 1960). Both techniques suffer some
22 drawbacks. The water vapor and air mixing scheme requires sample chambers that are typically
23 bulky and consequently cumbersome to use. The saturated salt solution technique provides only
24 discrete control in humidity levels and generally lacks a high degree of accuracy. In addition,
25 salt-induced corrosion leads to degradation of the chamber. Here a unique design is presented
26 that uses a temperature differential between the sample and a water bath, both of which are
27 contained in a sealed chamber to control the relative humidity. This simple design results in a
28 compact, self-contained apparatus that can be mounted on a variety of XRD instruments with
29 laboratory and synchrotron radiation for in-situ humidity/temperature (H/T) controlled studies.

46
47

48 The working principle of the in-situ H/T chamber is based on independent and precise
49 control of two temperature points within the sample environment. As schematically shown in
50 Fig. 1a, the chamber consists of a sealed and thermally insulated cylindrical shell connected to a
51 water reservoir (bath) via a small opening at the base (Sirota and Wu, 1996). The sample is
52 suspended in the center of the sealed chamber. The water bath is thermally insulated from the

64
65

1
2
3
4 sample shell, which enables independent control of the temperatures of the sample cell (T_1) and
5
6 the water bath (T_2). The temperature of the water bath sets the dew point of the sample
7
8 environment within the sealed housing, and hence the water vapor partial pressure, and from that
9
10 the relative humidity can be calculated as follows. The dew point of the sample environment
11
12 (T_2) sets the partial pressure of water vapor at the sample $P(T_2)$. The relative humidity of an
13
14 environment is defined as the ratio of the amount of water vapor present to the amount of water
15
16 vapor that can be held at T_1 . Assuming that water vapor acts as an ideal gas, this ratio is
17
18 equivalent to the ratio between the partial pressure of water vapor present to the partial pressure
19
20 of water vapor in a saturated environment. Hence:
21
22
23

$$24 \quad \%RH = 100\% * \frac{P(T_2)}{P(T_1)} \quad (1)$$

25
26 where T_2 is the dew point temperature, which is equal to the water bath temperature, T_1 is the
27
28 sample temperature, and $P(T_1)$ is the partial pressure of saturated water vapor at T_1 . When T_1 is
29
30 at or below T_2 , the sample is fully hydrated ($RH=100\%$), whereas for $T_1 > T_2$, the sample will
31
32 always be at partial humidity ($RH < 100\%$). By varying T_1 and T_2 one can set both the
33
34 temperature and humidity for the sample at precise increments, which makes this technique very
35
36 useful for in-situ experiments.
37
38
39
40
41
42
43
44

45 Phase transitions that occur at constant temperature and pressure, such as the transition
46
47 from liquid to vapor, also occur at a constant free energy, i.e. $\Delta G(P, T) = 0$, when the system is
48
49 in equilibrium. Under this condition, the vapor pressure is related to temperature via
50
51

$$52 \quad \left(\frac{\partial p}{\partial T} \right)_{\Delta G} = \frac{\Delta H}{T \Delta V} \quad (2)$$

53
54 where ΔH is the change of enthalpy of the transition, which is the molar latent heat of
55
56 vaporization, T is the temperature of the transition, and ΔV is the change of volume of the
57
58
59
60
61
62
63
64
65

1
2
3
4 substance. In the liquid to vapor transition, ΔV is approximately the volume of the vapor since
5
6 the vapor volume is much larger than the liquid volume. Assuming that ΔH is approximately
7
8 independent of temperature T , the partial pressures of saturated water vapor at any temperature
9
10 can be described by the Clausius-Clapeyron Equation (Haar et al., 1984):
11
12

$$14 \quad P(T) = P_0 e^{-\frac{\Delta H_{vap}}{RT}} \quad (3)$$

15
16 where P_0 is a constant, ΔH_{vap} is the molar latent heat of vaporization of water, R is the ideal gas
17
18 constant, and T is the absolute temperature. Fig. 1b shows the results of the fit to tabulated $P(T)$
19
20 values using the Clausius-Clapeyron equation (Haar et al., 1984). Because it is assumed that the
21
22 latent heat of vaporization of water ΔH_{vap} is constant with respect to temperature, there is a minor
23
24 deviation from the tabulated data. However, for the purposes of the experimental setup, this error
25
26 is considered negligible compared to other experimental variables, such as temperature accuracy
27
28 and uniformity. In the experiments to be presented, the vapor pressures were calculated by
29
30 linearly interpolating between two points of the tabulated curve.
31
32

33
34 The range of relative humidity that can be achieved with the chamber is dependent on
35
36 temperature. The practical range of operation (RH vs T), calculated using equations (1) and (3),
37
38 is shown in Fig.1 c. Although the principle described above can be applied to other solvents, for
39
40 practical purposes we will only consider the range using water. The temperature range is set to
41
42 be sufficiently above the freezing point and below the boiling point of water (10 °C - 95 °C). The
43
44 controllable range of RH increases at higher temperatures. At a sample temperature of 25 °C, the
45
46 achievable range of RH is 27.5%-98%. At 75 °C, the range is 2.3% - 98%. It should be noted
47
48 there are significant challenges for RH values > 95%, due to the very small temperature
49
50 difference between the sample and the water reservoir.

2.2 Sample Chamber Design

The mechanical design of the H/T chamber is illustrated in Fig. 2a. Good temperature stability is crucial to achieving precise humidity control. Thus the sample chamber consists of three concentric hollow cylinders (shells): the inner two made of aluminum and the outer shell made of plexiglas, which is not shown in the figure. The plexiglas outer shell acts merely as a thermal jacket, shielding the inner two cans from ambient air currents. The two aluminum cylinders are supported on a Teflon insulator, underneath which lies the water bath container. The water bath is heated or cooled to the desired dew point by a Peltier device mounted on an aluminum plate, which is used as both a support on the sample stage and a heat exchanger to draw excess heat away from the system. A Teflon spacer is placed between the water bath base and the aluminum cylinders to provide thermal insulation between the water bath and the ambient sample environment. A 0.5 inch (12.7mm) opening in the center of the spacer allows the water vapor to enter the sample chamber from the water bath.

To minimize x-ray attenuation, the inner cylinders are sealed with aluminized Kapton windows, and the plexiglas cylinder is covered with Mylar windows. However, x-ray scattering from the polymer windows exhibit a ring-like pattern, which could obscure the features of interest. To eliminate this parasitic background, small pass-through holes (~3mm in diameter) are punched through the windows at the beam position after the sample to prevent the intense direct beam from striking the windows. To seal the sample chamber, the through holes are covered with 4 μm thick pieces of aluminum foil. The thin aluminum foil is used because 1) it only negligibly attenuates the beam (~5%), and 2) its scattering signal is outside the region of interest for most biological systems and therefore does not contribute significantly to the

1
2
3
4 background. The scattering signal from the windows on the incident beam side of the chamber is
5
6
7 blocked by an aperture placed just before the sample.
8

9 The control diagram for the chamber is shown in Fig. 2b. Resistive heaters are used to
10
11 heat the ambient sample environment. The temperatures of the outer aluminum cylinder (sample
12
13 chamber) and the water bath are controlled by two separate Wheatstone bridge circuits with YSI
14
15 model 44011 thermistors as the control sensor. The resistive heaters used for the ambient sample
16
17 environment and the Peltier plate used for the water bath are powered by two separate power
18
19 supplies, one for each control circuit.
20
21
22

23 The temperature of the sample T_{sample} is controlled by setting the temperature of the outer
24
25 aluminum cylinder T_{cylinder} , and influenced to a small degree by the temperature of the water bath
26
27 $T_{\text{reservoir}}$. Because T_{sample} and $T_{\text{reservoir}}$ can be independently controlled, for the most part, there is
28
29 a vertical temperature gradient from the reservoir to the sample. Furthermore, the low thermal
30
31 conductivity of the aluminized Kapton windows can lead to non-uniform temperature on the
32
33 outer aluminum cylinder and water condensation on the interior surfaces of the windows at high
34
35 humidity levels. In such cases, additional heaters are necessary for the windows.
36
37
38
39

40 To account for such temperature gradients, three independent thermistors are used to monitor
41
42 the temperatures of the sample, the outer aluminum cylinder surface, and the water bath,
43
44 respectively; hence, a total of five temperature sensors are used in this chamber. The thermistors
45
46 used have an absolute accuracy of ± 0.2 °C. Applying the Clausius-Clapeyron Equation to relate
47
48 the relative humidity to the independent water bath and sample temperatures, the corresponding
49
50 absolute accuracy of relative humidity in the range of 65% or more is about $\pm 2\%$. The
51
52 temperature control stability is better than 0.01 °C, implying a relative humidity stability of
53
54
55
56
57
58 $\sim 0.1\%$.
59
60
61
62
63
64
65

2.3 Calibration

To calibrate the H/T chamber, the phase behavior of a freely suspended sample of the phospholipid 1-2-dimyristoyl-*sn*-glycero-phosphatidylcholine (DMPC) was investigated and compared with published results measured with conventional vapor mixing method (Sirota, et al., 1988; Smith, et al., 1988; Smith, et al., 1990). It is well established that DMPC forms two distinct lamellar phases at temperatures above 30 °C: L_{α} and $L_{\beta F}$. As shown schematically in Fig. 3c and 3d, respectively, the L_{α} phase is a lamellar phase in which the chains are fluid-like, whereas the $L_{\beta F}$ phase displays ordered chains. At a given temperature, it is known that DMPC undergoes a phase transition from L_{α} to $L_{\beta F}$ with decreasing relative humidity. This phase boundary was used as a reference for calibrating the chamber.

The structural transition from L_{α} to $L_{\beta F}$ is evident in the 2D x-ray diffraction data (Fig.3a and b), which was collected from the DMPC sample at the same temperature (36.6 °C) but at two slightly different RH levels near the phase boundary (70.4% and 69.4% RH, respectively). The data shows two sets of peaks corresponding to ordering along different molecular orientations: A series of sharp, roughly equally spaced, centro-symmetric arcs along the meridian represents the (00L) harmonics of the lamellar stacking of the lipid molecules, whereas in the equatorial direction, at much larger q (smaller spacing) the correlations between the alkyl tails gives rise to a broad arc of scattering intensity.

The difference between the two diffraction patterns becomes even more evident in projection scans along and perpendicular to the lamellar stacking direction, shown in Fig. 4e and f, respectively. Both the lamellar peaks and the chain-chain correlation peak sharpened as the relative humidity was reduced, indicative of the transition to the more ordered $L_{\beta F}$ phase. Due to

1
2
3
4 the diffusion-limited variation of humidity within the thickness of the sample, there is evidence
5
6 of coexistence of L_{α} and $L_{\beta F}$ domains in the data at lower humidity, as indicated by splitting of
7
8 the lamellar peaks. As the lipid transitions from the L_{α} phase to the $L_{\beta F}$ phase, the lamellar
9
10 spacing increases because the chains elongate as they lock into the ordered state, leading to a
11
12 progressively larger shift of higher-order harmonics toward lower scattering angles. The design
13
14 of the new H/T chamber was validated by the fact that the measured L_{α} to $L_{\beta f}$ phase boundary
15
16 (RH ~69.8%) was in good agreement with published data obtained with conventional vapor
17
18 mixing humidity control (Smith et al., 1990).
19
20
21
22
23
24

25 **3. In-situ X-Ray diffraction studies of oriented DNA fibers**

26
27

28
29 The H/T chamber was employed to study the hydration forces of oriented DNA molecules via in-
30
31 situ humidity-controlled x-ray fiber diffraction. It is well known that DNA (the Na salt)
32
33 undergoes a phase transition from the B-form to the A-form at 75% relative humidity at room
34
35 temperature (Franklin and Gosling 1953a,b; Fuller et al., 1965). The B-form, the structure of
36
37 which was first elucidated by Watson and Crick (Watson and Crick, 1953), is a double helix
38
39 structure with a pitch of 34 Å, diameter of 20 Å, and vertical rise of 3.4 Å per base pair. The A-
40
41 form is a double helix with a pitch of 28 Å, diameter of 23 Å, and rise per base pair of 2.6 Å
42
43 (Pattabhi and Gautham, 2002). Because of the high precision of determining molecular
44
45 separation from its well-characterized x-ray diffraction pattern, DNA has been extensively used
46
47 as a model system for studying hydration forces. The majority of the experiments had been
48
49 carried out by using the osmotic stress technique combined with x-ray diffraction in the
50
51 relatively dilute regime in which the DNA molecules were separated by more than 5 Å of water
52
53 (Parsegian et al., 1979; Rau et al., 1984; Rau and Parsegian, 1992). The DNA molecules were
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 believed to be in the B-form and were in general considered to be smooth, solid rods separated
5
6 by water. This simple model underpins the majority of force-distance-analysis so far. It is
7
8 unclear, however, whether the same hydration force relationship holds true for A-DNA, which
9
10 exists at much lower humidity. In addition, crystallographic studies of oligo-DNA molecules
11
12 have established that the DNA double helix holds a considerable amount of water in its grooves
13
14 (Egli et al., 1998; Guerri et al., 1998), which would argue against modeling DNA as smooth
15
16 rods. The current study aims to elucidate these effects with in-situ measurements at precise
17
18 humidity intervals and at much smaller DNA separation ($\sim 1.5 \text{ \AA} - 6 \text{ \AA}$) than previous studies. It
19
20 is expected that in this regime, the assumption that the DNA molecules are smooth rods is no
21
22 longer valid and one must consider the structural details within the grooves of the DNA to
23
24 interpret the hydration force data.
25
26
27
28
29

30
31 For filamentous molecules, the quality of diffraction data improves with increasing
32
33 degree of alignment. An in-situ fiber puller was constructed to produce aligned DNA fibers for
34
35 H/T studies in the cell, based on the method first described by Franklin and Gosling (Franklin
36
37 and Gosling, 1953a,b). This technique has also been widely used to align discotic liquid crystals
38
39 (Safinya et al., 1984, 1985). The puller shown in Fig. 4a consists of a cup containing the DNA
40
41 solution and a moving pin. The DNA solution used to draw the fibers consisted of 40 weight%
42
43 Calf Thymus DNA and 60 weight% buffer, a 100 mM solution of KCl. At this concentration,
44
45 DNA forms a columnar hexagonal phase and is most conducive to growing fibers (Blanc et al.,
46
47 2001; Livolant et al., 1991a,b). The speed at which the fiber is drawn directly influences the size
48
49 and quality of the fiber and is controlled by using a computer-controlled step motor. A typical
50
51 fiber was about 5 mm in length, and between 300 μm and 500 μm thick. The fiber, intact on the
52
53 fiber puller assembly, was next placed in the humidity-controlled chamber and was left to

4 equilibrate for at 1 to 20 hours before x-ray data was taken. Each fiber was viewed under
5
6 polarized microscopy to check for alignment. Fig.4b and c show optical microscopy images of a
7
8 DNA fiber viewed under crossed polarizers (The sample was rotated 45 degrees in the two
9
10 images). The dramatic difference in brightness confirms the presence of strong birefringence
11
12 due to alignment of the highly anisotropic DNA molecules. It is evident that the fiber actually
13
14 consisted of a bundle of smaller, more crystalline micro-fibers that are axially aligned. The
15
16 orientation of the micro-fibers in the direction perpendicular to fiber axis is random, thus giving
17
18 rise to a diffraction pattern equivalent to the rotationally averaged diffraction pattern from a
19
20 single crystal fiber.
21
22
23
24

25
26 A series of 2D x-ray diffraction patterns collected in-situ from an aligned DNA fiber
27
28 inside the H/T oven at different humidity levels is shown in Fig.5. It is worth noting that the
29
30 experiments were performed on a single fiber sample typically over a period of several days,
31
32 sometimes with very small humidity level changes in between measurements. The diffraction
33
34 data shown is representative of more than 10 sets of repeat measurements. The striking “X”-
35
36 shaped scattering feature, most obvious in the top four panels, is characteristic of the helical
37
38 structure of DNA in the B-form (Franklin and Gosling, 1953a,b; Atkins, 1994). As the humidity
39
40 level decreases below 87%, the diffraction feature of the A-form appears. Between 82.7%-86.7%
41
42 RH, the diffraction data is a superposition of both A- and B-forms, indicating co-existence. At
43
44 RH < 80%, the structure is pure A-form, which is characterized by much more crystal-like
45
46
47
48
49
50
51
52 diffraction patterns.

53 Equatorial peaks in the diffraction data are consistent with hexagonal packing of DNA
54
55 molecules in the plane normal to the helical axis. In the data for the B-form, the helical layer
56
57 lines are the main features, indicating that the neighboring DNA molecules lack correlation in
58
59
60
61
62
63
64
65

1
2
3
4 the longitudinal (axial) direction. Thus, it is likely that the B-form DNA molecules are in the
5
6 hexagonal columnar phase, with molecules free to slide past each other (Livolant et al., 1989). In
7
8 comparison, the data for A-form DNA at lower humidity levels show distinct spots that are
9
10 consistent with a “lattice” type of arrangement in which the neighboring DNA molecules are
11
12 registered in both the longitudinal and lateral directions. Even though the DNA helices are more
13
14 ordered in this phase (with density correlation between neighboring molecules), it cannot be
15
16 considered a 3D crystal, since there is no specific base-pair to base-pair locking because of
17
18 sequence variation. As we show later (in section 4.2), these molecular packing details have
19
20 important implications when the hydration force curve is derived from the diffraction patterns.

25
26

27 **4. Discussions**

28 4.1 B to A form transition

29
30 The transition from B-form to A-form is examined by plotting the change of the double helix
31
32 pitch as a function of relative humidity. As shown in Fig.6a, the onset of the transition from B- to
33
34 A-form occurs at ~87% RH within a narrow range (~0.3% RH) and is discontinuous. At RH
35
36 between 82.7% and 86.7% (vertical dashed lines), there is evidence of coexistence of B and A
37
38 forms in the diffraction data. In the mixed phase diffraction data, it was possible to extract the
39
40 pitch parameters for both forms, which are plotted on the same curve using different symbols. At
41
42 RH<80%, the signatures of the B-form are no longer detectable. The absence of any diffraction
43
44 signature other than that from B- and A-form DNA during the transition confirms that there are
45
46 no intermediate states between the B- and A-form. Thus, the B to A conformational change can
47
48 be considered as a first order phase transition (Fuller et al., 2004). This result is consistent with
49
50 previous experimental measurements and also with more recent molecular dynamics studies
51
52 (Banavali and Roux, 2005; Dickerson and Ng, 2001; Fuller et al., 2004). It should be noted that
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 although it is expected that the transition is fully reversible, the experiments described here were
5
6 only conducted along the path from high to low RH.

8
9

10 11 4.2 Hydration force in DNA

12
13 The humidity-driven structural changes in the DNA fiber have been used as a model system to
14
15 study the hydration force between linear molecules. The removal of water through the drying
16
17 process, i.e. the reduction of the relative humidity costs energy due to the change in the chemical
18
19 potential of the water vapor. This change in chemical potential can be calculated from the
20
21 relative humidity as shown by Parsegian and others (Parsegian et al., 1979; Smith et al., 1988,
22
23 1990) as:

$$24 \Delta\mu = RT \ln(P_{\text{water-vapor}}/P_{\text{saturation}}) = RT \ln(\text{RH}) \quad (4)$$

25
26 where $\Delta\mu$ is the change of the chemical potential in a mol volume of water vapor, R is the ideal
27
28 gas constant, T is the absolute temperature, and RH is the relative humidity of the environment.

29
30 $\Delta\mu$ has the unit of energy (work) per unit volume (e.g. ergs / cm³) but can also be expressed as a
31
32 differential pressure or force per unit area: dyne/cm² by using the relation 1 erg = 1 dyne cm.
33
34 Thus, the change in chemical potential is directly related to the hydration force, which is
35
36 believed to be the dominant force maintaining the DNA rod-to-rod separation. The microscopic
37
38 origin of this force is not fully understood (Parsegian and Zemb, 2011; Podgornik et al., 1994). It
39
40 is known, however, to have an exponential dependency on the distance between DNA molecules
41
42 of the form (Parsegian et al., 1979; Smith et al., 1988, 1990): $f_{\text{hyd}} \sim e^{-d_w/\lambda}$, where d_w is the
43
44 thickness of the water layer between DNA molecules and λ is the hydration force decay constant.
45
46
47
48
49
50
51
52
53
54
55

56
57 To extract the relevant force-distance curve from the data, the equatorial peaks in the
58
59 fiber diffraction patterns were used to determine the axial spacing (separation) between the DNA
60
61
62
63
64
65

1
2
3
4 molecules. A hexagonal packing model was used to index the peaks, resulting in a single lattice
5
6 parameter a (interhelical spacing) that describes the axial separation (center-to-center) between
7
8 neighboring DNA molecules in the plane perpendicular to the fiber axis. Since we are concerned
9
10 with only equatorial reflections, the lattice parameter can be derived from the measured d -
11
12 spacing of the first peak $d_{(1\ 0\ 0)}$ by the equation $a=2d_{(1\ 0\ 0)}/\sqrt{3}$. In the B-form, this hexagonal
13
14 packing model is well accepted. Here this model also works well for A-form equatorial data and
15
16 can be justified as follows. A crystallographic indexing of the A-form data requires a c-centered
17
18 monoclinic lattice (Fuller, 1965). However, since the hydration force is interpreted only in terms
19
20 of rod-to-rod distance, we need to concern ourselves only with in-plane packing (i.e. average
21
22 interhelical spacing). Thus the monoclinic cell reduces to a centered 2D rectangular cell. The in-
23
24 plane lattice constants (a,b) , which vary with hydration and ionic strengths, are generally quite
25
26 close to being hexagonal with $a/b \sim \sqrt{3}$. Additionally, the true crystalline A-form only manifests
27
28 at the very low end of humidity (<80%) in the current study. Considering that the fiber sample is
29
30 composed of multiple micro-fibers, we must also take into account rotational averaging in-plane.
31
32 Taken together, these effects justify using a simpler hexagonal indexing scheme to calculate the
33
34 isotropic axial separation between DNA rods in the fiber sample even in the A-phase.
35
36
37
38
39
40
41
42
43

44 The intensity profiles of the first equatorial peak at several RH points near the B- to A-
45
46 form transition are shown in Fig.6b. At RH=88.6%, the sample is in the B phase in which all
47
48 DNA are in the B-form. The $(1\ 0\ 0)$ hexagonal peak is sharp and has high intensity. At
49
50 RH=82.7%, the majority of the DNA in the sample is in the A-form (A phase). The peak, which
51
52 is taken as the $(1\ 0\ 0)$ peak in the pseudo-hexagonal lattice, is broader and weaker. In between
53
54 these two RH values, the system undergoes the B- to A-form transition with co-existence of both
55
56 forms, with the percentage of A phase increasing as RH is lowered. It is interesting to note that
57
58
59
60
61
62
63
64
65

1
2
3
4 during the transition the (1 0 0) peak position remains unchanged, indicating a fixed axial
5 separation between DNA molecules either in the A- or B-form, while the peak intensity
6
7 gradually decreases.
8
9

10
11 The hydration force curve derived from the DNA fiber diffraction data as a function of
12 humidity is shown in Fig.7. The force (in log scale), represented as a change in chemical
13 potential per unit volume (ergs/cm³), which is equivalent to a differential pressure (dyne/cm²,
14 force per unit area), is plotted against DNA interhelical spacing d . For hexagonal packing, d is
15 equal to the 2D hexagonal lattice constant a . Two features stand out in the graph and merit
16 further discussion. First, it can be seen that the data points fit well to straight lines both in the A
17 and B phases, as expected due to the exponential dependence of the hydration force vs
18 separation. The slopes of the two lines, which are described as force decay constants (λ), are 1.96
19 Å and 1.94 Å, for A- and B forms of the DNA, respectively. The difference in the decay lengths
20 in the two forms is within experimental uncertainty and both values agree well with the generally
21 accepted decay constant of ~ 2 Å found in a large number of systems studied previously
22 (Parsegian and Zemb, 2011).
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40

41 The high concentration of DNA (and fairly high salt concentration) in the sample resulted
42 in measured axial separation ranging from 21.8 Å – 25.3 Å. As shown in Fig. 7, the B-form to A-
43 form conversion starts at an axial separation of $d_{AB} = 23.4$ Å, which remains constant through the
44 transition. This particular axial spacing at which both A- and B-form DNA co-exist is
45 meaningful in two ways. First, if we subtract the diameter of B-DNA (20 Å) from d_{AB} , we find
46 that the surface separation for B-DNA is equal to 3.4 Å, indicating that neighboring B-DNA are
47 within one hydration shell of each other. Second, it is perhaps no coincidence that d_{AB} is only
48 slightly larger than the diameter of A-DNA (23 Å). This suggests that at even lower humidity
49
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 (i.e. smaller axial separation), in the A phase there is interpenetration of the DNA helices. The
5
6 fact that force decay constant in both the A and B phase is essentially the same suggests that
7
8 hydration force continues to play a dominant role in maintaining DNA rod-to-rod separation
9
10 even in the tightly packed, and much drier A phase.
11
12

13
14 The second noticeable feature in Fig. 7 is the vertical shift in the force curves for A and B
15
16 phases. This shift (chemical potential change) is related to the fact that the A-DNA and B-DNA
17
18 are in different free energy states (Banavali and Roux, 2005). Since the hydration force curves in
19
20 both A and B phases have the same force decay constant ($\sim 2 \text{ \AA}$), it is reasonable to assume that
21
22 the same force-distance relationship also holds during the B to A transition. Thus, using the same
23
24 exponential formula one could model the vertical shift of the force curve in the A phase by an
25
26 effective reduction in water layer thickness Δd_w as
27
28

$$29 \quad \Delta d_w = (d_A - d_B) + \lambda[\ln(-\Delta\mu_B) - \ln(-\Delta\mu_A)] \quad (5)$$

30
31
32 Where d_A and d_B are the diameters of A- and B-DNA, respectively, $\lambda=2 \text{ \AA}$ is the force decay
33
34 constant, $\Delta\mu_B$ and $\Delta\mu_A$ are the chemical potential values corresponding to the onset of pure B and
35
36 A phases, respectively (end points on the vertical rise in the transition regime). Based on data
37
38 shown in Fig. 7, a Δd_w value of 2.4 \AA was obtained. The significance of this value will become
39
40 evident in discussions below.
41
42
43
44
45

46
47 To examine the hydration force in the A and B phases, it is necessary to derive the actual
48
49 water layer thickness values upon which the hydration force depends ($f_{hyd} \sim e^{-d_w/\lambda}$). Generally
50
51 this is done by converting the axial spacing d into wall-to-wall separation d_w by subtracting the
52
53 diameter of the DNA double helix. For the B phase, this method produces reasonable values,
54
55 however for the A phase it results in non-physical negative distances since the interhelical
56
57 separation can be smaller than the diameter of A-DNA. This suggests that there is
58
59
60
61
62
63
64
65

1
2
3
4 interpenetration of the helices in the A phase and we must derive d_w using a different approach.
5
6 To do this, we shall consider the difference in packing between the A- and B-forms of DNA and
7
8 its consequences in hydration force calculation.
9

10
11 It is important to realize that the measured “hydration force” is actually the net
12
13 summation of all the work related to removing water from the system. Considering the
14
15 hexagonal packing of DNA, one realizes that there is actually a whole range of d_w (wall-to-wall
16
17 separation or water layer thickness) in the structure. However, due to the exponentially decaying
18
19 nature of the hydration force, the dominant contribution would come from parts of the structure
20
21 where d_w is small. In other words, it is essential to define the minimal separation (water layer
22
23 thickness) in the structure. In the B-form, the DNA molecules are able to slide in the axial
24
25 direction (columnar hexagonal packing). This effectively averages the density over the entire
26
27 length of the molecule. In addition, the wall-to-wall separation is sufficiently large that
28
29 contribution from the water inside the DNA grooves can be neglected. Thus treating the DNA in
30
31 the B-phase as a solid rod (a common practice in biophysical research) is quite reasonable. In
32
33 this model, the effective minimum separation is $d_w=d-d_B$, where d is the measured axial
34
35 separation of DNA and d_B is the diameter of DNA in the B-form ($d_B=20 \text{ \AA}$).
36
37

38
39 In the A phase, the axial registration of the neighboring DNA molecules in the crystalline
40
41 lattice “locks” the relative position of DNA helices with respect to each other and the molecules
42
43 are in closer contact. Thus, the thickness of water layer is no longer just determined by the outer
44
45 diameter of the A-DNA. One must take into account the water within the A-DNA double helix.
46
47

48
49 It is well established that the DNA double helix has major and minor grooves that can
50
51 hold substantial amount of water (Egli et al., 1998; Guerri et al., 1998). We surmise that it is the
52
53 locking of the relative positions of neighboring A-DNA molecules in the A phase that enabled
54
55
56
57
58
59
60
61
62
63
64
65

interpenetration. We can model the contribution of the water inside the grooves as having the effect of reducing the A-DNA diameter to $d'_A = d_A - \Delta d_w$, where $\Delta d_w = 2.4 \text{ \AA}$ is the effective water layer thickness change during the B to A phase transition as derived from experimental data earlier. This value can also be estimated directly from structural parameters of A-DNA as follows. In the cross sectional view through the center of the c-axis, the A-DNA can be modeled as a rectangle with an unit area of $d_A P$, where $d_A = 23 \text{ \AA}$ is the diameter of A-DNA and $P = 28 \text{ \AA}$ is the pitch. On this rectangle, we can approximate the major and minor grooves in A-DNA as having triangular profiles with depths and widths of d_M, W_M and d_m, W_m , respectively. The effective solid area of the A-DNA cross section can be derived by subtracting the area of the grooves:

$$A = d_A P - d_M W_M - d_m W_m$$

The effective solid rod diameter of the A-DNA is given by $A/P = d_A - (d_M W_M - d_m W_m)/P$. Correspondingly, one obtains $\Delta d_w = (d_M W_M - d_m W_m)/P$. Using the published parameters of A-DNA (major groove: depth 13.5 \AA , width 2.7 \AA ; minor groove: depth 2.8 \AA , width 11.0 \AA) (Pattabhi, 2002), we arrive at a value for $\Delta d_w = 2.41 \text{ \AA}$, which matches the value derived from experimental data. Thus, the “effective diameter” of A-DNA becomes 20.6 \AA for the purpose of deriving wall-to-wall separation in the A phase. It should be noted that the above calculation also confirms that the contribution from the narrow and deep major groove to the hydration force is rather small compared to the wide and shallow minor groove.

By applying different schemes as described above to derive the water layer thickness in the A and B phases, we arrive at a force-distance curve shown in Fig. 8. As expected, the A and B phase data points are essentially on a continuous line. Note that the surface separation d_w between DNA molecules varies from $\sim 1.5 \text{ \AA}$ to 6 \AA , a range unprobed by previous

1
2
3
4 measurements (Parsegian and Zemb, 2011). In the A and B co-existence regime the effective d_w .
5
6 d_w is calculated by $d_w = d - (w_A d_A + w_B d_B)$, where d_A and d_B are the effective diameters of A- (20.6Å)
7 and B-DNA (20Å), respectively, and w_A and w_B are the corresponding phase fractions, which
8
9 were calculated by comparing A- and B-DNA peak intensity values with diffraction data in the
10
11 pure A- and B-DNA phases.

16 17 **5. Materials & Methods**

18 19 20 5.1 X-ray diffraction

21
22 For the experiments described in this paper, the H/T chamber was mounted on a motorized X-Y-
23
24 Z sample stage which was fitted on a Huber 4-circle goniometer with a Rigaku rotating anode x-
25
26 ray source (UltraX18HF, 0.3 mm point focus size). An Osmic™ confocal max flux multilayer
27
28 monochromator was used to select Cu K $_{\alpha}$ radiation from the source and a MAR345 image plate
29
30 detector was used to collect the diffraction data from the sample. The typical sample to detector
31
32 distance is 18 cm, corresponding to a maximum scattering wave vector q_{\max} of 3.0 Å $^{-1}$. Careful
33
34 control of the incident beam divergence and profile by using a pair of slits allowed us to achieve
35
36 a q_{\min} of ~0.1 Å $^{-1}$, enabling both intermediate SAXS and WAXS studies on the same instrument.

44 45 5.2 DMPC lipid calibration sample preparation

46
47 The DMPC (Avanti Polar Lipids) was mixed with high resistivity water (18.2 MΩcm) to a ratio
48
49 of 30 weight% water and 70 weight% DMPC. This mixture was spread over a heated ~5mm
50
51 thick aluminum plate containing a 3 mm diameter hole; the plate was heated to a temperature to
52
53 ensure that the DMPC solution would be in the L $_{\alpha}$ phase. The sample thickness was between 1
54
55 to 2 mm. Once this solution was set, the sample plate was mounted in the chamber, and the
56
57 sample ambient environment was set to 37 °C, the dew point was set to 33 °C, and the sample
58
59
60
61
62
63
64
65

1
2
3
4 was left in the chamber to equilibrate for at least 12 hours. Subsequently, the sample
5
6 temperature and relative humidity were set, and left to come to equilibrium (within 2 to 3 hours),
7
8 and finally x-ray data was taken with an exposure time of two minutes.
9

10 11 5.3 DNA fiber preparation 12

13
14 The DNA solution used to draw the fibers consists of 40 weight% Calf Thymus DNA and 60
15
16 weight% buffer, a solution of 100 mM KCl in high resistivity (18.2 MΩcm) water. The mixture
17
18 was placed in the cup of the fiber puller, and a fiber was initiated by dipping the pin into the cup
19
20 containing the solution and pulling it up by hand. Once the fiber was initiated, the assembly was
21
22 placed in an airtight cell in which the fiber could be elongated by drawing more solution at a
23
24 controlled pulling speed of 100 μm per minute.
25
26
27

28 29 **6. Conclusions** 30

31 A unique design for a compact humidity and temperature controlled chamber suitable for in-situ
32
33 x-ray scattering studies was presented. The H/T sample chamber was utilized to investigate the
34
35 phase behavior of aligned DNA fibers as a function of hydration. The axial separation between
36
37 DNA molecules was examined with consideration of structural differences in A and B
38
39 conformations to generate a hydration force curve with an exponential decay length of $\sim 2 \text{ \AA}$, in
40
41 good agreement with measurements by other methods. The results confirm that in the A-phase in
42
43 which there is interpenetration of DNA helices the hydration force continues to play a dominant
44
45 role in setting the DNA axial spacing.

5
6

7 **Fig. 1** Operating principle of the differential temperature control humidity chamber. (a) The
8 relative humidity is derived based on the partial vapor pressure at the sample held at a
9 temperature at or above the water reservoir temperature, which sets the dew point of the sample
10 environment. (b) Fit to tabulated water vapor pressure values. The Clausius-Clapeyron
11 Equation was used to fit data taken from published tabulated data (Haar et al., 1984). (c)
12 Calculated range of temperature and humidity values that can be achieved with the sample
13 chamber.

24 **Fig. 2** Mechanical design and control diagram of the humidity temperature chamber. (a) The
25 assembly consists of three concentric cylinders (only the two inner shells are shown). The outer
26 insulating case is used to improve temperature stability against ambient fluctuations. (b) The
27 temperature of the sample is set by controlling the temperature of the outer aluminum cylinder,
28 and the relative humidity at the sample position is set by controlling the dew point at the sample
29 via the temperature of the reservoir. Resistive heaters are placed on the middle aluminum
30 cylinder to enhance temperature stability, and the layer of air between this and the innermost
31 cylinder surrounding the sample dampens temperature fluctuations.

14
15 (The fiber sample was rotated by 45 degrees between b and c).
16
17

18
19
20 **Fig. 5** In-situ 2D x-ray diffraction data collected at different relative humidity levels from an
21 aligned DNA fiber sample using the H/T chamber at $T=30^{\circ}\text{C}$. The top four panels show
22 characteristic features of the B-form DNA whereas the bottom panels at lower humidity are in
23 mixed B+A or pure A-form as indicated.
24
25
26
27
28

29
30 **Fig. 6** Conversion of B-DNA to A-DNA driven by reduced humidity. (a) Pitch of DNA double
31 helix as a function of humidity showing the transition from B- to A-form starting at $\text{RH} \sim 87\%$.
32
33 Between $\text{RH} \sim 82\% - 87\%$ (dashed vertical lines) there is coexistence of A- and B-forms. Error
34 bars for RH were determined by propagating thermistor uncertainties through the Clausius-
35 Clapeyron equation while uncertainties in pitch were determined by calculating the detector's q_z
36 resolution at the first and second layer lines of B- and A-DNA respectively. (b) Intensity profiles
37 of the first equatorial peak in the humidity range of pure B-DNA, to a coexistence of B- and A-
38 DNA, and finally to pure A-DNA. In the co-existence range (between $\text{RH} 83\% - 87\%$) the peak
39 position (hence interhelical separation) remains unchanged (vertical line).

49
50
51

52 **Fig. 7** The dependence of inter-helical spacing on the log of the differential pressure exerted on
53 the DNA molecules. The pressure is directly related to change in the chemical potential due to
54 relative humidity. The linear correlation exhibited in both phases confirms the characteristic
55 exponential dependence of hydration force on separation distance, with a decay length of $\lambda \sim 2\text{\AA}$.

65

1
2
3
4 **Fig.8** The hydration force curve for both A and B phases. In the B-DNA phase, the wall-to-wall
5 separation (minimum water layer thickness) is derived by subtracting the diameter of B-DNA
6
7 (20 Å) from the interhelical spacing. In the A-DNA phase, d_w is derived by first subtracting the
8
9 diameter of A-DNA (23 Å), then adding 2.4 Å to account for the contribution from water within
10
11 the major and minor grooves in A-DNA. In the A and B co-existence regime the effective d_w is
12
13 calculated by $d_w = d - (w_A d_A + w_B d_B)$, where d_A and d_B are the effective diameters of A- (20.6Å) and
14
15 B-DNA (20Å), respectively, and w_A and w_B are the corresponding phase fractions.
