"Appointed as the first lecturer in Structural Crystallography at Cambridge (1927) ... crystallographic techniques to organic molecules, starting with oestrin and sterol compounds including cholesterol in 1929, he analysed vitamin B1 (1933), pepsin (1934), vitamin D2 (1935), the sterols (1936), and the tobacco mosaic virus (1937), ... also worked on the structure of liquid water, showing the boomerang shape of its molecule (1933). With Dorothy Hodgkin in 1934, took the first X-ray photographs of hydrated protein. Max Perutz arrived as a student from Vienna in 1936 and started the work on haemoglobin."

Cell Dimensions of Ordinary and ‘Heavy’ Ice

I have recently made accurate determinations of the cell dimensions of crystals of ordinary and ‘heavy’ ice (D₂O). Single crystals were used. The apparatus consisted of a small Dewar flask mounted on the axis of a Bernal photogoniometer, and filled with a mixture of acetone and solid carbon dioxide. A holder of copper wire attached to the bottom of the flask contained a capillary tube of Lindemann glass, into which a drop of water was sealed. The crystal was grown by inserting the glass tube into its holder in contact with the cooling mixture; its growth was observed with a polarising microscope, and it was thawed and grown again until a good single crystal was obtained. The direction of fastest growth was the normal to (11̅2), so that this direction generally grew along the axis of the tube. There was a steep temperature gradient in the crystal; at the holder it was very nearly at –78°C, while its top, about 3–3 cm. above this, was at the melting point, and was in contact with a layer of liquid. The spacings could thus be determined at different temperatures.

Preliminary photographs showed that the structure of crystalline D₂O is the same as that of ordinary ice. The setting of the crystal was made by means of oscillation photographs. The exact spacings were determined from reflections at nearly 180°, recorded with a back-camera. For α, the plane (5050) was used with copper Kα radiation, for c, (0008) with cobalt Kα. The spacings were measured at –66°C, and at the melting-point. The results are given below, with an estimate of the probable limits of experimental error (values for D₂O at 0°C, are calculated from those at 4°C by interpolation).

Megaw on thermal expansion

The Thermal Expansions of Certain Crystals with Layer Lattices
Author(s): Helen D. Megaw
Reviewed work(s):

The Thermal Expansions of Certain Crystals with Layer Lattices.

By HELEN D. MEGAW, M.A., Yarrow Research Student of Girton College, Cambridge.

(Communicated by A. Hutchinson, F.R.S.—Received May 5, 1933.)

[PLATE 2.]

The methods for the determination of linear expansion coefficients which are applicable to anisotropic substances fall into two main groups, the optical and the X-ray methods. Of these the former have hitherto been much more extensively used. They consist essentially in measuring the change in distance between two plane surfaces of the crystal. Thus, Fizeau* investigated a large number of crystals by an interferometer method, and much of the subsequent work on single crystals has been done by modifications of this method. An optical lever method was applied by Roberts† to the measurement of the expansion of single crystals of bismuth. The X-ray method determines directly the change in lattice spacing of the crystal.

Megaw on thermal expansion: Niobates

Megaw on thermal expansion: Niobates

Three hypothetical structures, illustrating different effects of expansion: (a) blocks having an expansion different from the matrix; (b) framework with tilted polyhedra; (c) blocks capable of tilting within a 'soft' matrix.

(ii) The structure shown in Fig. 1(b) consists of identical squares tilted with respect to one another by the angle $BAC = \phi$. If $AB = \ell$, $AD = a = 4\ell \cos \phi$. Now suppose each square expands homogeneously, and also, independently, the tilt angle changes with temperature: the overall linear expansion coefficient along $AD$ is

$$\frac{1}{X} \frac{dL}{dt} - \sin \phi \frac{d\phi}{dt}$$

(2)

The first term is the expansion coefficient of the square itself, the second a consequence of the crumpling of the framework.

Megaw on thermal expansion: Relations to bond strength

$q = \text{CN/charge, referred to by Megaw as Pauling valence}$

$q = 8$ for CsCl
$q = 6$ for NaCl
$q = 4$ for CaF$_2$

These are all examples of linear expansions only, with no angular changes.

Zr in octahedra and W in tetrahedra. 50% thermal ellipsoids displayed.

Crystal Structure of Barium Titanate

It is well known that barium titanate belongs to the group of compounds having structures of the perovskite type. The ideal perovskite structure (G8 in the "Strukturbericht") has a simple cubic lattice, with one formula-weight per cell, the atomic parameters being as follows: 2-valent cation, (0,0,0); 4-valent cation, (1/4,1/2,1/4); oxygen, (0,1/2,0), (1/4,0,1/4), (1/4,1/4,0). It was early recognized that for many of these compounds, including perovskite (CaTiO₃) itself as well as barium titanate, the structure was not truly cubic, but was actually a slightly deformed modification of it. Perovskite itself is generally believed monoclinic; the structure has recently been determined in detail by Naray-Szabo, who finds a monoclinic unit cell with all its edges doubled relative to the unit cell of the ideal structure. No detailed work on barium titanate has hitherto been published, and it was thought of interest to investigate it.

Powder photographs of the synthetic material taken in a 19 cm.-diameter camera with copper Kα radiation provided the data for determining the structure.

The structure is tetragonal, the dimensions of the unit cell at 20° C., for a typical sample of material, being as follows: \( a = 3.9860 \pm 0.0005 \) kX., \( c = 4.0263 \pm 0.0005 \) kX., \( c/a = 1.0101 \pm 0.0002 \). This cell contains one formula-weight, BaTiO₃. The atomic parameters are the same as in the ideal cubic structure. The relationship between the tetragonal and cubic structure is close; the tetragonal unit cell may be simply derived from the cubic by stretching it homogeneously by about 1 per cent along one tetrad axis, which becomes the c axis.

This close relationship suggests that a transition to the cubic structure may occur at higher temperatures. This was verified from photographs taken with a high-temperature camera. At 200° C., barium titanate has the ideal cubic structure, with \( a = 4.040 \pm 0.0005 \) kX.

Further work is in progress.

I wish to express my gratitude to Sir Lawrence Bragg for allowing me the use of the high-temperature camera in his laboratory. I wish also to thank Mr. J. A. M. van Moll (head of the Material Research Laboratory) and the directors of Philips Lamps, Ltd., for permission to publish this work.
